Asymmetric Information, Employer Learning, and the Job Mobility of Young Men

Ye Zhang†

Job Market Paper

December 12, 2006

Abstract

This paper develops an asymmetric employer learning model in which endogenous job mobility is both a direct result of intensified adverse selection and a signal used by outside employers to update their expectations about workers’ productive ability. The previous literature on asymmetric employer learning builds on two-period mover-stayer models and finds little empirical evidence of the differential impacts of ability and education on wages across tenure levels. This paper extends the mover-stayer framework by allowing the employment history to be observed by recruiting firms in a three-period model. I derive new empirical implications regarding the relationship between wage rates, ability, schooling and overall measures of job mobility. Testing the model with data from the National Longitudinal Survey of Youth 1979 (NLSY-79), I find strong evidence supporting the three-period asymmetric employer learning model.

*I am most grateful to Jeffrey Smith for his insightful comments, continued support and encouragement. I am also particularly indebted to Judith Hellerstein for her invaluable guidance and help throughout the preparation of this paper. I have benefited too from discussions with Pedro Carneiro, Jonah Gelbach, John Rust, Seth Sanders, William Evans, and workshop participants at the University of Maryland. All remaining errors are my own.

1 Introduction

Asymmetric and imperfect information characterizes almost every aspect of modern labor market, and economists have been interested in investigating their consequences ever since the seminal work of Akerlof (1970) and Spence (1973). This paper studies an employer’s private information about a worker’s productivity and argues, theoretically and empirically, that early-career job mobility plays an important role in the employer learning process about employees’ productive ability.

In a world where the information about workers’ productivity is incomplete, it is not possible for a company that is hiring to assess the value of a job candidate by his unobserved innate ability. Instead, the potential worker’s employment history and other forms of information about his productivity, such as resumes and reference letters, usually serve as the basis for recruitment. This information imperfection directly motivates the statistical theory of discrimination\(^1\) where firms distinguish between individuals with different observable characteristics based on statistical regularities. Although some information about the worker’s ability is available to all the firms in the market, it is reasonable to imagine that the incumbent employer gets to accumulate further information about the worker’s productive ability after the production begins, and then updates his beliefs accordingly. His subsequent wage offers and layoff/firing choices are conditioned on the revised expectations of the worker’s productivity. When the current employer and potential employers set their wage rates according to different information sets, the worker’s job mobility is endogenously determined by the wage offers from the two sides, and his employment history conveys information regarding his unobserved productivity. The job change pattern of the worker, which is an inevitable consequence of the information asymmetry, provides outside employers with an additional tool to go somewhat beyond the “veil of ignorance” and learn about the worker’s productive ability. As intuitively appealing as it sounds, previous research on this topic has neglected the learning process of outside employers through the worker’s employment history.

The main contribution of this paper, and the key feature of my employer learning model, is to

---

treat endogenous job mobility\textsuperscript{2} as an additional source of information about a worker’s productivity that is available to the outside employers.\textsuperscript{3} In the context of asymmetric information, job changing as an outcome of market adverse selection can be used by potential employers to assess the quality of the worker. By offering workers with different mobility histories different wage rates, market selection intensifies over time. In contrast, under the hypothesis that learning is symmetric between incumbent and outside employers\textsuperscript{4}, job separations have no implications for the worker’s expected productivity and mobility plays no role in employer learning. While earlier research on asymmetric information in the labor market recognizes that one consequence of private learning is that workers who switch firms are of lower quality than workers who stay with their employers, they rely on two-period mover-stayer type models and ignore the informational content of job changes which helps outside employers to dynamically acquire extra information about worker productivity.

Using the 1979 cohort of the National Longitudinal Survey of Youth (NLSY-79), and taking advantage of its unique cognitive ability measure, the Armed Forces Qualification Test (\textit{AFQT}) score, which provides a summary of basic math and literacy skills that is not observed by the employers, I test the intensified adverse selection model by examining whether the relationship between the test score and job mobility weakens as workers age. The average quality of workers who change jobs equals that of workers who do not if the learning is symmetric. Additionally, if adverse selection does not worsen with the accumulation of labor market experience as implied by the two-period mover-stayer asymmetric employer learning model, then the correlation between the ability measure and the probability of changing jobs should stay constant over time. On the contrary, a model in which job mobility serves as an ability signal to outside employers not only implies that the more frequent are job turnovers, the lower is the quality of the worker, but it also predicts that ability plays less and less of a vital role in the mobility decision with each year that

\textsuperscript{2}The model endogenizes job mobility by adding non-pecuniary job characteristics to the worker’s utility function. For similar approach to model mobility, see Neal (1998), Acemoglu and Pischke (1998), and Schonberg (2005).

\textsuperscript{3}Gibbons and Katz (2001) allow outside firms to learn the reasons for prior job separations and condition their wage offers on them, but in reality, discerning the cause of a prior job change is much more challenging than obtaining the employment history of a job applicant.

\textsuperscript{4}The symmetric learning models of Farber and Gibbons (1996) and Altonji and Pierret (2001) do not consider worker mobility at all.
the worker spends in the labor market. Thus, this implication empirically differentiates the three models.

I modify the empirical model of Farber and Gibbons (1996) and Altonji and Pierret (2001) by incorporating into the wage regressions the frequency of prior job separations. I show that there is a significant difference between frequent job movers and occasional movers in terms of how ability affects the way that the incumbent and outside firms set their wage rates conditional on labor market experience. This finding is contrary to the public employer learning model because the assumption that the incumbent and recruiting firms have the same amount of information about the worker’s ability indicates that the AFQT score affects wage determination for every firm in the same fashion given experience. This finding is also not consistent with the two-period mover-stayer model of private learning. If learning is indeed by job tenure, Schonberg (2005) shows that the coefficient on the interaction between tenure and the test score is positive because only the wage offer from the incumbent firm, not that of the outside employers, reflects the new information about the worker’s productivity. But, if the outside employers do not exploit the job mobility history as an additional source of information to distinguish low quality workers from high quality job candidates, the difference of the impacts of ability on wage rates between the incumbent and outside firms is identical for workers with different mobility levels given the same experience level. However, if the outside firms’ wage offers depend on the employment history as described by the three-period model presented in this paper, the information asymmetry is partially resolved by its own outcome and for more frequent job changers, the outside employers have a more accurate signal about their productivity so the employer learning more closely resembles public learning for this group of individuals. According to my three-period model, learning progresses for employers at both ends of the labor market. The incumbent employer updates his expectations of the worker’s productivity by observing his output and relies less and less on easily observable characteristics, while the outside potential firms learn through the job mobility history and also depend less and less

5Mincer and Jovanovic (1981) use the frequency of prior moves as a control for individual heterogeneity when estimating the returns to job seniority. I use the coefficients on the interaction terms between prior mobility, test score, job tenure, and years of schooling to test the three-period asymmetric employer learning model.
on variables like years of schooling. The substitution between employment history for schooling
as a productivity signal implied by my model allows me to test it by examining the impact of
education on wages for individuals with different job turnover patterns.

The paper unfolds as follows. Section 2 provides a review of the employer learning literature
and Section 3 presents the employer learning model where a worker’s employment history is used
by outside firms to revise their expectations about the worker’s productivity, and contrasts the
empirical implications of my model with those of the public learning and two-period mover-stayer
models. Section 4 describes the data and Section 5 presents empirical evidence. Section 6 con-
declines.

2 Previous Work

While it seems plausible that prospective employers may be less informed about the productivity
of the worker than the current employer, it is the assumption about how the outside firms learn
that divides the literature on employer learning. The phrases “symmetric employer learning” or
“public learning” refer to the body of research that assumes away asymmetric information and
instead assumes that all market participants, incumbent or outside, have the same amount of
information about the worker’s productivity at each point in time and that the labor market oper-
ates competitively. Examples of early theoretical analysis under the hypothesis of public employer
learning are Freeman (1977) and Harris and Holmstrom (1982). Another set of studies, including
this paper, assume that there is some degree of information asymmetry and that the incumbent
employer has superior information about the employee’s ability. Under this assumption, recruiting
firms have an informational disadvantage relative to current employers. How the outside firms use
the information contained in the worker’s employment history to minimize this disadvantage moti-
vates this paper. In the literature, efforts have been made to examine how “asymmetric employer
learning”, or “private learning”, might generate inefficient job assignments within the firm, these
include the models laid out by Waldman (1984), Milgrom and Oster (1987), and Bernhart (1995).
Other theories, such as Greenwald (1986) and Lazear (1986), focus on the analogous implications for wage dynamics and job separations.

Two influential papers made empirical breakthroughs in testing the employer learning model: Farber and Gibbons (1996) and Altonji and Pierret (2001). Working under the hypothesis of pure symmetric employer learning, they deliver testable empirical implications that are consistent with the observed patterns in the data for experience gradients, education, and ability in a wage regression that are hard to reconcile with a simple human capital model. Their models predict that, at labor market entry, firms rely on easy-to-observe variables that are correlated with productivity to determine wage rates. Thus, the coefficient on a variable correlated with productivity which is not observable to employers but is observed by economic analysts should increase with labor market experience. The same argument leads to the decreasing time path of the coefficient on the easy-to-observe variable that is correlated with ability if the hard-to-observe measure of ability is included in the wage regression.\(^6\) Both papers use the NLSY-79 to test their theoretical predictions and obtain broadly supportive results. Their methodology also has been applied to datasets outside of the United States. For example, Bauer and Haisken-DeNew (2001) find some support for the symmetric employer learning model in German data for blue-collar workers, but not for white-collar workers; Galindo-Rueda (2002) obtains similar findings using data from the UK for approximately the same time period as that considered by Altonji and Pierret (2001). More recently, Lange (2005) develops an econometric model to estimate the speed of employer learning,\(^7\) also under the pure symmetric learning assumption. He finds that employers are able to reduce their average expectation error about the productivity of a worker by 50% over the first three years, he concludes that this is rather fast. It is noteworthy that if the current employer and outside employers hold different perceptions about a worker’s productivity, then his conclusions may change.

Empirical research on labor market asymmetric information is sparse and far from conclusive.

\(^6\)Altonji and Pierret (2001) specify their learning model in logarithms while Farber and Gibbons (1996) specify the model in levels and derive that wages should follow a martingale.

\(^7\)In an earlier paper, Altonji and Pierret (1998) recognize that the speed of employer learning plays a crucial role in statistical discrimination. They argue that the observed coefficient patterns in their earnings equation are consistent with a fast speed of employer learning and that this limits the contribution of signaling to the returns to education.
Gibbons and Katz (2001) test the asymmetric learning hypothesis by comparing the earnings loss of workers who are laid off versus those who are displaced for exogenous reasons, like plant closing. Under the assumption that information concerning a worker’s ability is private to the current employer, outside market participants infer that laid-off workers are of low quality and label them as “lemons”, no such inference is warranted for exogenous job leavers. Since the pre-displacement wages do not differ by cause of displacement for the two groups of workers, their asymmetric learning model predicts a greater wage loss for layoffs than for those displaced by plant closing. Their empirical examination using the CPS Displaced Workers Supplements (DWS) clearly supports their model predictions.\(^8\)

Rodriguez-Planas (2004) extends the adverse selection model of Gibbons and Katz (2001) by allowing recalls of laid-off workers to their original employers and offers a new test of the importance of asymmetric information in the labor market. She argues that if employers have discretion over whom to recall, high-ability workers are more likely to be recalled and may choose to remain unemployed rather than to accept a low-wage job offered early in their unemployment spell. If so, unemployment can serve as a signal of productivity. In this case, her model suggests that unemployment duration may be positively related to post-displacement wages even among workers who are not recalled. In contrast, because workers displaced through plant closings cannot be recalled, a longer duration of unemployment should not have a positive signaling benefit for such workers. Her empirical results using the 1988-2000 DWS reveal that the earnings and unemployment duration experiences of the two groups behave in the predicted way and are consistent with asymmetric information in the labor market.

In a paper closely related to my study, Schonberg (2005) extends the framework of Farber and Gibbons (1996) and Altonji and Pierret (2001) to accommodate the situation in which employer learning is private by endogenizing the mobility decision of the worker. She builds a two-period mover-stayer model and tests it by adding tenure variable to the wage regression and examining

---

\(^8\)Hu and Taber (2005) recently challenge the results of Gibbons and Katz (2001) by showing the difference in wage loss between exogenous job leavers and layoffs varies dramatically by race and gender. They offer heterogeneous human capital and taste-based discrimination as possible explanations for the observed patterns for African Americans and females.
whether the effects of education and ability on wage offers differ for incumbent employers and outside firms. She finds only limited empirical evidence to support her asymmetric information model for the workers with higher education, after she includes interactions between schooling and the test score variables with higher-order terms in job tenure.9

3 The Asymmetric Employer Learning Model

3.1 A Basic Two-Period Model

First, let’s consider a simple two-period employer learning model set up in the spirit of Greenwald (1986) and Schonberg (2005) to highlight the way in which asymmetric information and adverse selection distort market transactions. I extend the model to three-period setting in Subsection 3.2. This model assumes the productivity of individual $i$ in firm $j$, $\chi_{i,j}$, is given by $\chi_{i,j} = \eta_i + \delta_{i,j}$, where $\eta_i$ denotes the $i$th worker’s time-invariant innate ability and $\delta_{i,j}$ is the quality of the worker-firm match. The population distributions of $\eta_i$ and $\delta_{i,j}$ are independent and are common knowledge to all market participants. I further assume that $\eta_i \sim N(\mu_\eta, \sigma_\eta^2)$, $\forall i$ and $\delta_{i,j} \sim N(\mu_\delta, \sigma_\delta^2)$, $\forall i, j$. Jobs are treated as pure search goods in this model10 and match productivity is known ex ante. In another words, there is no further information on match quality generated in the model as the match proceeds. Following the job matching literature, a new value of $\delta_{i,j}$ is drawn from its distribution with each job change and the successive drawings are independent. This guarantees that the worker’s prior employment history is not relevant in assessing his $\delta_{i,j}$ in a newly formed match.11

The risk-neutral workers are also heterogeneous with regard to their non-pecuniary utility

9She does not find evidence of asymmetric learning for high school dropouts and high school graduates in her sample.

11Another line of job search and matching models treats match-specific productivity as an experience good; see, e.g., Johnson (1978), Jovanovic (1979a), and Moscarini (2003), where match quality is not known ex ante but is learned over time as the job is “experienced”. While particularly tractable and well tested, in order to concentrate attention on employer learning and sequential adverse selection, and to avoid the complications caused by employee’s time varying perceptions of job quality, I model match quality as an inspection good in this paper.
component, \( \theta_{i,j,t} \), associated with job \( j \) for time period \( t \). The inclusion of this taste parameter is in line with most of the existing work on asymmetric employer learning and is part of an easy way to endogenize mobility. As explained by Greenwald (1986), the “random” quit behavior generated by this type of heterogeneity is critical to the existence of equilibrium turnover. In particular, it facilitates trading even in the presence of adverse selection so that the market does not break down completely as in Akerlof (1970). In this model, the non-pecuniary utility measure is assumed to be transitory and workers draw a new value of \( \theta_{i,j,t} \) in each period for each job. This taste shock may refer to personal problems with colleagues and supervisors, the working environment, health and other benefit programs, etc. I specify the distribution of \( \theta_{i,j,t} \) as \( N(0, \sigma_{\theta}^2) \) for any \( i, j, t \).

Wage rates are determined on the spot market and long-term contracts of any sort are assumed away. At the beginning of the first period, wages are offered simultaneously by all of the recruiting employers. Firms do not see \( \chi_{i,j} \) although they know \( \delta_{i,j} \) upon inspection. In addition, after production takes place, the \( i \)th worker’s output for period 1 in firm \( j \), \( y_{i,j,1} \), becomes available to the incumbent firm. The public learning models of Farber and Gibbons (1996) and Altonji and Pierret (2001) assume that the information held by employers is symmetric and all of the firms in the market observe the same sequence of output \( (y_{i,j,1}, y_{i,j,2}, \ldots, y_{i,j,t}) \) through period \( t \). In contrast, in my model, the productivity signal is only observed by the worker’s current employer. This noisy measurement, \( y_{i,j,1} = \chi_{i,j} + \epsilon_{i,j,1} \), is then used by the current firm to update his expectation of the \( i \)th individual’s productivity. With an additional assumption of \( i.i.d \) normal distribution for \( \epsilon_{i,j,t} \), the Bayes’s rule yields the expected productivity at the end of period one from the perspective of the incumbent employer:

\[
E(\chi_{i,j} \mid y_{i,j,1}) = \frac{\sigma^2_{\eta}}{\sigma^2_{\eta} + \sigma^2_{\epsilon}}(\mu_{\eta} + \delta_{i,j}) + \frac{\sigma^2_{\eta}}{\sigma^2_{\eta} + \sigma^2_{\epsilon}}y_{i,j,1}.
\]

The posterior mean is simply a weighted average of the prior expectation of the worker’s productivity and the noise-ridden signal, where the weights depend on the relative sizes of the prior

\[12\text{I use employer and job interchangeably in this paper. Empirically, the term “job” refers to any position within a given employer rather than to a particular position with that employer. The work history file in NLSY-79 does not provide enough information to distinguish job position changes from employer changes.}\]
variance and the variance of the noise term $\epsilon_{i,j,1}$. The posterior variance $\text{Var}(\chi_{i,j} \mid y_{i,j,1})$ is known to be $\frac{\sigma_{\epsilon}^2 \sigma_{\eta}^2}{\sigma_{\epsilon}^2 + \sigma_{\eta}^2}$, which is independent of the realization of $y_{i,j,1}$.

At the beginning of period two, potential employers make wage offers first, the current employer observes the offers and makes a counter offer. This timing of events in wage determination is standard in the literature dealing with asymmetric information.\(^{13}\) While the key empirical implications of the model remain valid if the second-period wage offers are made simultaneously by the incumbent and outside firms, they are no longer attainable if the current employer makes the first move. In this case, the incumbent firm loses his informational advantage and reveal the productivity of the workers to the entire market by tying wage offers to the productivity signals that only he observes. To avoid a host of game-theoretical strategic considerations that lie beyond the scope of this paper, I maintain this conventional assumption on the timing of wage offers.

Observing the wage offers and the new draws of the non-monetary utility component measures $\theta_{i,2}^j$, individual $i$ makes his mobility decision. Assuming risk-neutrality, the utility of job $j$ consists of the sum of the wage offer from employer $j$ and the non-pecuniary taste measure, $w_{i,2}^j + \theta_{i,2}^j$, where $j = c, o$ with $c$ denoting the current employer and $o$ the potential alternative employer. Thus, worker $i$ moves away from his current firm if and only if $w_{c,2}^i + \theta_{c,2}^i \leq w_{o,2}^i + \theta_{o,2}^i$. Making use of the distributional assumption about the unobserved non-pecuniary heterogeneity, the probability of moving is $\Phi(\frac{w_{o,2}^i - w_{c,2}^i}{\sqrt{2} \sigma_\theta})$. All workers are employed in both periods and retire at the end of the second period.

Working backwards from the second period and suppressing the individual subscript $i$, with the updated expectation of the worker’s productivity as well as the outside wage offer $w_{2}^o$ in hand, the optimization problem for the incumbent firm is

\[
\max_{w_{2}^c} \left( \frac{\sigma_{\epsilon}^2}{\sigma_{\eta}^2 + \sigma_{\epsilon}^2} (\mu_\eta + \delta_c) + \frac{\sigma_{\eta}^2}{\sigma_{\eta}^2 + \sigma_{\epsilon}^2} y_{c,1} - w_{c}^o \right) (1 - \Phi(\frac{w_{2}^o - w_{2}^i}{\sqrt{2} \sigma_\theta})),
\]

while the outside employer maximizes

\[
\max_{w_o^2} \left( \mu_o + \delta_o - w_o^2 \right) \Phi \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma} \right).
\]

(3)

Manipulation of the first-order conditions yields

\[
w_c^2 = \frac{\sigma_c^2}{\sigma_\eta^2 + \sigma_c^2} (\mu_c + \delta_c) + \frac{\sigma_\eta^2}{\sigma_\eta^2 + \sigma_c^2} y_{c,1} - \sqrt{2} \sigma \theta \frac{1 - \Phi \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma \theta} \right)}{\phi \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma \theta} \right)},
\]

(4)

and

\[
w_o^2 = \mu_o + \delta_o - \sqrt{2} \sigma \theta \Phi \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma \theta} \right) \frac{\phi \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma \theta} \right)}{\phi \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma \theta} \right)}.
\]

(5)

The monotone hazard rate feature of normal random variables, \(d \left( \frac{1 - \Phi(\theta)}{\phi(\theta)} \right) / d\theta < 0\), implies the quasi-concavity of the objective functions so that the first-order conditions are sufficient for the maximization problems. The monotone hazard rate also guarantees that the two reaction functions defined by the two first-order conditions both have a positive slope less than one and that there is at most one intersection. The equilibrium exists and is unique.\(^{14}\)

The wage offer of the current employer depends on the productive signal sent by the worker. His first-order condition implies

\[
\frac{\partial w_c^2}{\partial \eta} = \frac{\sigma_\eta^2}{\sigma_\eta^2 + \sigma_c^2} > 0,
\]

(6)

and

\[
\frac{\partial w_c^2}{\partial \delta_c} = \frac{1}{1 - d \left( \frac{1 - \Phi \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma \theta} \right)}{\phi \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma \theta} \right)} \right) / d \left( \frac{w_o^2 - w_c^2}{\sqrt{2} \sigma \theta} \right)} > 0.
\]

(7)

\(^{14}\)This equilibrium is different from the Nash equilibrium of Greenwald (1986) due to our differing assumptions regarding the “random” quit behavior. His analysis relies on the assumption that the probability of quitting equals one if the outside offer is greater than the wage offered by the incumbent firm and equals a fixed value \(\mu\) if the current employer offers a higher wage rate. As a result of that, firms in his model simply retain high ability workers by matching their outside offers.
In the context of match quality as an inspection good, the higher is the innate ability, the higher is the wage offered by the incumbent firm. The relationship between the current employer’s wage offer and the worker’s ability is not as strong as the relationship between the incumbent’s wage offer and match quality. This simply follows from the different learning mechanisms attached to the individual’s innate ability and to the match-specific productivity. Job match quality is learned instantly, without error ex ante, while ability has to be inferred from a series of noisy signals. As pointed out by Lange (2005), the parameter $\frac{\sigma^2}{\sigma^2_\eta + \sigma^2_\epsilon}$ plays a central role in the updating process of expected productivity. It represents the noisiness of the initial assessment of productivity relative to the noisiness of the subsequent signals. It is clear from (6) that if subsequent signals are more noisy than the initial expectation, that is, the smaller is $\frac{\sigma^2}{\sigma^2_\eta + \sigma^2_\epsilon}$, the lower the weight the incumbent firm places on innate ability in wage setting.

At the same time, private information prevents potential employers from obtaining updated expectations of unobserved productivity, as a result, the outside wage offer does not vary with $\eta$. Nevertheless, the relationship between the outside wage offer and match-specific productivity is positive, i.e.

$$\frac{\partial w^o_2}{\partial \delta_o} = \frac{1}{1 + d(\Phi(\frac{w^o_2-w^c_2}{\sqrt{2}\sigma_\theta}))/d(\Phi(\frac{w^c_2-w^o_2}{\sqrt{2}\sigma_\theta}))} > 0,$$

which is intuitive given the assumption about the nature of job match quality. The relationship between mobility and ability generated by this model embodies adverse selection, so that

$$\frac{\partial \Phi(\frac{w^o_2-w^c_2}{\sqrt{2}\sigma_\theta})}{\partial \eta} = -\frac{1}{\sqrt{2}\sigma_\theta} \phi(\frac{w^o_2-w^c_2}{\sqrt{2}\sigma_\theta}) \frac{\partial w^c_2}{\partial \eta} < 0.$$

That is, the probability of moving to another employer at the beginning of the second period is higher for less able workers. Again, taking the derivative with respect to current firm’s match quality,

$$\frac{\partial \Phi(\frac{w^o_2-w^c_2}{\sqrt{2}\sigma_\theta})}{\partial \delta_c} = -\frac{1}{\sqrt{2}\sigma_\theta} \phi(\frac{w^o_2-w^c_2}{\sqrt{2}\sigma_\theta}) \frac{\partial w^c_2}{\partial \delta_c} < 0.$$

Equation (10), along with (8) captures the notion of a “good match” in the sense that it pays
better and survives longer. Match quality has little impact on the implications of asymmetric employer learning highlighted by (7) and (9). Topel and Ward (1992),\textsuperscript{15} using longitudinal employee-employer data, indicate that wage gains at job changes average about 10% and account for about one third of total wage growth during the first ten years in the labor market. This evidence should not be seen as contrary to the predictions of the asymmetric information model, as the match-specific productivity $\delta_{i,j}$ in our model does allow between-job wage growth, while their study does not deal with the quality of the workers across mobility levels.

To complete the model, I assume that the wage setting game on the entry-level labor market resembles the standard inspection good job matching models and the public learning models. Before period one, none of the firms in the labor market knows more about the productivity of the worker than the initial expectation, the wage offers therefore do not depend on ability. Without loss of generality, I assume only two potential employers $j = J, K$ are competing for workers on the entry-level market. This particular case can be extended readily to the $N$-firm case. If the firms and workers share the same discount factor $\beta$, the $i$th individual’s expected utility when working for firm $J$ is

$$w_1^J + \theta_1^J + \beta \left[ \Phi\left(\frac{w_2^K - w_2^K}{\sqrt{2}\sigma_\theta}\right)(w_2^K + \theta_2^K) + (1 - \Phi\left(\frac{w_2^K - w_2^K}{\sqrt{2}\sigma_\theta}\right))(w_2^J + \theta_2^J) \right],$$

(11)

where switching $J$ and $K$ yields the utility from working for firm $K$.

Taking the difference between the utilities from employer $J$ and employer $K$ produces the probability that firm $J$ attracts the $i$th worker, $\Phi\left(\frac{w_1^J - w_1^K}{\sqrt{2}\sigma_\theta}\right)$. Therefore, the profit maximization problem for employer $J$ can be written as

$$\max_{w_1^J} \Phi\left(\frac{w_1^J - w_1^K}{\sqrt{2}\sigma_\theta}\right) \left[ \mu_\eta + \delta_J - w_1^J + \beta E_{\eta,\epsilon}(1 - \Phi\left(\frac{w_2^K - w_2^K}{\sqrt{2}\sigma_\theta}\right)(\frac{\sigma_\sigma^2}{\sigma_\eta^2 + \sigma_\epsilon^2}(\mu_\eta + \delta_J) + \frac{\sigma_\eta^2 y_{i,1}}{\sigma_\eta^2 + \sigma_\epsilon^2} - w_1^J)) \right],$$

(12)

where $E_{\eta,\epsilon}$ denotes the expectation with respect to random variables $\eta$ and $\epsilon$. Replacing subscript $J$ with $K$ defines the optimization problem facing firm $K$. The symmetry implies that in the entry-

\textsuperscript{15}See Bureau of Labor Statistics (2006) for similar results from the NLSY-79.
level market equilibrium, both firms offer the same wage conditional on match quality, just as in the case of public learning and better match quality commands a higher wage rate. Combining match-specific productivity and adverse selection on the unobserved innate ability, it follows immediately that although a “mismatch” leads to a lower wage and an early separation, job matching models do not predict that movers are of lower quality than stayers, an important prediction from the two-period model.

3.2 A Three-Period Extension with Empirical Implications

While the two-period mover-stayer model does capture how private information held by the current employer affects the worker’s mobility decision and wage determination, it is silent about the role of job mobility in sequential market trading, and it treats potential recruiting firms as completely “passive”. The extension to a three-period setting allows the employment history of the workers on the second-hand labor market to serve as another signal to outside firms and provides an additional channel for recruiting employers to learn about the unobserved productivity of the workers. The two-period model suggests that worker ability and job mobility are negatively correlated because of adverse selection. It is conceivable that outside employers take prior job mobility into account when they make subsequent wage offers. The three-period extension also sharply contrasts with the match quality story of job mobility, in which the prior employment history is independent of the quality of a new match. Here, prior employment history is the driving force behind dynamic adverse selection.

From the perspective of the potential employers, at the end of period two, the workers can be distinguished by their mobility decisions in the previous period. Conditioned on each of the two possible values of the number of job changes, \( m = 0, 1 \), the bidding procedure is completely comparable to the one at the end of the first period. The only difference is that the recruiting firms now know that the distribution of \( \eta \) is different for workers with different \( m \) because market selection takes place at the end of period one. For workers with \( m = 1 \), that is, those who change...
jobs at the end of period one, the expected productivity becomes

$$E(\chi_j \mid m = 1) = E(\eta \mid w_2^o \leq w_2^o + \theta_2^o - \theta_2^c) + \delta_j. \quad (13)$$

Given that $\frac{\partial w^c_2}{\partial \eta} > 0$ and that everything else in the conditioning set of the expectation of $\eta$ is independent of $\eta$, the end-of-period-one adverse selection shifts the ability distribution of the $m = 1$ workers toward the left. Similarly, asymmetric employer learning shifts the distribution of $\eta$ for the stayers toward the right.

Meanwhile, the incumbent firms of workers with $m = 0$ continue learning in the Bayesian style. Their updated expectation is

$$\frac{\sigma^2_\epsilon}{2\sigma^2_\eta + \sigma^2_\epsilon}(\mu_\eta + \delta_c) + \frac{2\sigma^2_\eta}{2\sigma^2_\eta + \sigma^2_\epsilon} \frac{(y_{c,1} + y_{c,2})}{2}. \quad (14)$$

For the current employer of workers with $m = 1$, expected productivity takes the form of (1). With repeated market transactions as in the three-period model, potential employers make offers to workers with $m = 1$ according to

$$\max_{w_3^{c',1}} (E(\eta \mid w_2^c \leq w_2^o + \theta_2^o - \theta_2^c) + \delta_{c'} - w_3^{c',1})\Phi\left(\frac{w_3^{c',1} - w_3^{c',1}}{\sqrt{2\sigma^2_\theta}}\right), \quad (15)$$

and make offers to workers with $m = 0$ according to

$$\max_{w_3^{o',0}} (E(\eta \mid w_2^c > w_2^o + \theta_2^o - \theta_2^c) + \delta_{o'} - w_3^{o',0})\Phi\left(\frac{w_3^{o',0} - w_3^{o',0}}{\sqrt{2\sigma^2_\theta}}\right), \quad (16)$$

where $c'$ and $o'$ denote the incumbent and outside employers at the end of period two and the numerical superscript on $w_3$ represents the value of $m$. We further obtain the corresponding optimization problems for the current firms

$$\max_{w_3^{c',1}} \left(\frac{\sigma^2_\epsilon}{\sigma^2_\eta + \sigma^2_\epsilon}(\mu_\eta + \delta_{c'}) + \frac{\sigma^2_\eta}{\sigma^2_\eta + \sigma^2_\epsilon} y_{c',2} - w_3^{c',1}\right)(1 - \Phi\left(\frac{w_3^{c',1} - w_3^{c',1}}{\sqrt{2\sigma^2_\theta}}\right)), \quad (17)$$
and
\[
\max_{w_{3,0}^{c}} \left( \frac{\sigma_{e}^{2}}{2 \sigma_{\eta}^{2} + \sigma_{e}^{2}} (\mu_{\eta} + \delta_{e}) + \frac{\sigma_{\eta}^{2}}{2 \sigma_{\eta}^{2} + \sigma_{e}^{2}} (y_{e,1} + y_{e,2}) - w_{3,0}^{c} \right)(1 - \Phi \left( \frac{w_{3,0}^{c} - w_{3,0}^{o}}{\sqrt{2} \sigma_{\eta}} \right)).
\]  

Comparing (15) and (16) with (3), it is easy to see that the outside wage offers for \( m = 0 \) individuals exceed those for \( m = 1 \) workers because \( E(\eta \mid w_{2}^{c} > w_{2,i}^{o} + \theta_{i}^{o} - \theta_{i}^{c}) > E(\eta \mid w_{2,i}^{c} \leq w_{2,i}^{o} + \theta_{i}^{o} - \theta_{i}^{c}) \). Movers at the end of period one are adversely selected and have a worse \( \eta \) distribution than workers with \( m = 0 \). The labor market recognizes this by offering them lower wage rates at the end of the second period. In the basic two-period framework, the equilibrium wage on the second-hand market does not depend on \( \eta \), as suggested by (3). Earlier research on asymmetric employer learning stops there and compare quality between movers and stayers in terms of some aptitude test scores such as the \( AFQT \) score. However, that approach neglects the intensified adverse selection that is induced by the information contained in the worker’s employment history and does not generate empirical implications about the time path of the effect of ability on the wage offers from the incumbent and from the outside employers. The three-period extension argues that the outside market equilibrium wage also correlates increasingly with unobserved ability and that market selection aggravates dynamically, so that

\[
\frac{\partial \Phi \left( \frac{w_{3}^{o} - w_{3}^{c}}{\sqrt{2} \sigma_{\eta}} \right)}{\partial \eta} = \frac{1}{\sqrt{2} \sigma_{\eta}} \phi \left( \frac{w_{3}^{o} - w_{3}^{c}}{\sqrt{2} \sigma_{\eta}} \right) \left( \frac{\partial w_{3}^{o}}{\partial \eta} - \frac{\partial w_{3}^{c}}{\partial \eta} \right) < 0.
\]  

Although (19) is negative,\(^ {16} \) meaning that workers with lower values of \( \eta \) are still more likely to change jobs, the additional positive component \( \frac{\partial w_{3}^{o}}{\partial \eta} - \frac{\partial w_{3}^{c}}{\partial \eta} \) means fewer job changes after the second period than after the first period.\(^ {17} \) There is an enormous amount of heterogeneity among movers and an important tool for potential recruiting firms detecting this heterogeneity is job mobility history. A typical two-period analysis, such as Schonberg (2005), predicts that the ability gradient of the job separation probability remains constant over time. In contrast, in the three-period case, incumbent firms gradually lose their informational advantage due to the accumulation of knowledge

\(^{16} \)This is because the current employer still holds more information about \( \eta \) relative to outside market, so, \( \frac{\partial w_{3}^{o}}{\partial \eta} - \frac{\partial w_{3}^{c}}{\partial \eta} < 0 \).

\(^{17} \)See Greenwald (1986) for a similar argument.
about \( \eta \) by outside employers and employer learning on the market place converges to the public learning model over time. The intensified adverse selection implies a decreasing effect of innate ability on the job change probability. It is also obvious from (19), but still worth mentioning that if the output sequence \((y_{j,1}, y_{j,2}, ..., y_{j,t})\) is available to all the firms, then \( \frac{\partial w_{o,1}^c}{\partial \eta} = \frac{\partial w_{c,1}^c}{\partial \eta} \) and \( \frac{\partial \Phi(\sqrt{2\sigma_\theta})}{\partial \eta} = 0 \) for any \( t \). When the information is imperfect but symmetric, the ability distribution is identical across mobility levels and the worker’s job changing decision depends on the match quality \( \delta \) and the non-pecuniary job characteristics \( \theta \).

The first-order condition for (18) combined with (6) allows us to obtain

\[
\frac{\partial w_{o,1}^c}{\partial \eta} = \frac{2\sigma_\eta^2}{2\sigma_\eta^2 + \sigma_\epsilon^2} + \left[ \frac{d(1-\Phi(\frac{w'_{o,1}^c - w_{o,1}^c}{\sqrt{2\sigma_\theta}}))}{d(\frac{w'_{o,1}^c - w_{o,1}^c}{\sqrt{2\sigma_\theta}})} \frac{\partial w_{o,0}^c}{\partial \eta} \right] > \frac{\partial w_{o,1}^c}{\partial \eta}.
\]

This inequality explicitly spells out employer learning, that is, for workers staying with their initial employers for the entire three periods, wage rates depend more and more on unobserved productivity. Moreover, and perhaps more importantly, this increase in the correlation between wages and ability is larger than that in the pure symmetric employer learning model. To see this, notice that the numerator of \( \frac{\partial w_{o,0}^c}{\partial \eta} \) has two parts. The first term comes from the current employer learning more over time, as argued by Farber and Gibbons (1996) and Altonji and Pierret (2001), i.e. \( \frac{2\sigma_\eta^2}{2\sigma_\eta^2 + \sigma_\epsilon^2} > \frac{\sigma_\eta^2}{\sigma_\eta^2 + \sigma_\epsilon^2} \), where \( \frac{\sigma_\eta^2}{\sigma_\eta^2 + \sigma_\epsilon^2} \) appears as the numerator of (6). The second term is a special feature of this model and follows directly from the market feedback of the job mobility decision. It represents the additional premium put on unobserved productive ability by the current employer because he knows that outside recruiting firms can partially learn about the ability of the workers via the employment history. Existing asymmetric employer learning models have been unable to lay this out clearly and convincingly because they do not take into account the signaling effect of job mobility on outside wage offers.

\(^{18}\)Jovanovic (1979a) (footnote 11, p. 982) reads “...in other words, the model does not imply that “movers” should do worse than “stayers” even though empirically this appears to be true...”
For workers who change jobs after period one, the increase in the correlation between market wage rates and innate ability $\eta$ over time also holds. The wage determination process in (3) implies that for $m = 1$ workers, wage offers for period two are constant over $\eta$ because only $\mu_\eta$ enters (3), but the story told by (15) and (17) is that whether or not these workers decide to change jobs at the end of the second period, it is always the case that $\frac{\partial w_o^{c,1}}{\partial \eta} > 0$ and $\frac{\partial w_o^{o,1}}{\partial \eta} > 0$. The three-period asymmetric employer learning model agrees with the public learning models and the earlier two-period analysis of private employer learning in that wages are increasingly correlated with the unobserved productivity as labor market experience accumulates. It departs from existing studies in terms of its implications for the differential returns to ability for people with different job changing patterns, even conditional on labor market experience and job tenure.

Public information makes $\frac{\partial w_o^2}{\partial \eta} = \frac{\partial w_o^2}{\partial \eta}$ and $\frac{\partial w_o^{c,1}}{\partial \eta} = \frac{\partial w_o^{c,0}}{\partial \eta} = \frac{\partial w_o^{o,1}}{\partial \eta} = \frac{\partial w_o^{o,0}}{\partial \eta}$, at any point in time, for workers with the same amount of labor market experience. All the wage offers, no matter where they come from, depend on $\eta$ in the same way, given the independence of $\eta$ and match quality $\delta$. And, individuals with different patterns of prior job separations have the same returns to the unobserved productive ability. The two-period mover-stayer model favored by Schonberg (2005) recognizes that innate ability has a stronger impact on wage offers for incumbent firms than for outside employers, and the difference is greater as the informational advantage of the incumbent firm increases. Based on this implication, Schonberg (2005) predicts a positive coefficient on the variable that interacts the $AFQT$ score and job tenure in a wage regression. While in general this intuition still holds for the three-period model, when potential employers on the outside market take job mobility history into consideration at the end of period two, the informational advantage of the current firm is reduced and the reduction amount is higher for the workers with more frequent job changes. The more information the outside firms have, the smaller is the difference between the impacts of ability on wages for the incumbent versus outside firms. This implication is not consistent with mover-stayer model in which learning by recruiting employers is ruled out. Thus, the signaling effect of the prior job moves implies a negative coefficient for the variable which interacts the test score, job tenure, and frequency of job mobility.
One real world application of employer learning models is to study statistical discrimination, where firms distinguish among workers on the basis of easily observable variables that are correlated with productivity like years of education, gender, and race. Altonji and Pierret (2001) describe the intuition of such analyses succinctly:

“As employers learn about the productivity of workers, s [which is schooling] will get less of the credit for an association with productivity that arises because s is correlated with z [variable like AFQT score that is initially unobserved, but is positively correlated with both s and output], provided that z is included in the wage equation with a time dependent coefficient and can claim the credit.”

Note that because the education level is part of the firm’s initial information set and is incorporated into the determination of first-period wages, the subsequent innovations in wages can not be forecast from the years of schooling. The empirical regularity of declining time path of the returns to schooling arises solely out of the relationship between education and unobserved innate ability. To include easily observed time-invariant characteristics like schooling in the model, I can redefine productivity as

\[ \chi_j = rs + \eta + \delta_j, \]  

where \( s \) denotes the years of schooling. Keeping everything else in the model unchanged, the time path of the returns to \( \eta \) is shown to be increasing as firms accumulate more information, regardless of whether it is symmetrically or asymmetrically distributed between the incumbent and potential employers. This learning effect on the impact of ability spills over to the schooling variable that firms use to statistically discriminate among new employees following the same logic as in Altonji and Pierret (2001) given \( \text{cov}(\eta, s) > 0 \), thus, the model predicts that the coefficient on \( s \) in a wage regression declines with labor market experience when an ability measure unobservable to employers is included.

Unlike years of schooling, which is a time-invariant ability signal known to all the employers

---

\(^{19}\)Farber and Gibbons (1996) make this point and predict a zero coefficient on the interaction term between education and experience when the residualized AFQT score is included in a wage regression.
upon market entry, the job mobility history serves as a time-varying signal to the outside firms in the three-period model. Just like the output sequence \((y_{j,1}, y_{j,2}, \ldots, y_{j,t})\), the information contained in the employment history is utilized by potential hiring firms to evaluate the productivity of the workers. The fact that learning by the outside firms increasingly makes the time-invariant signal \(s\) redundant is another special feature of the three-period model. Traditional analyses ignore the informational content of prior job moves and imply that the path of the effect of education on wages is independent of job mobility, conditional on experience and job tenure. The signaling effect of employment history, however, predicts a negative coefficient associated with the interaction between years of schooling and the frequency of job mobility in a wage regression.

4 The Data

The empirical work is based on White, Black, and Hispanic males from the 1979-2000 waves of the National Longitudinal Survey of Youth (NLSY-79). A key feature of the NLSY-79 is that in addition to the detailed information on family background, scholastic achievement, and labor market outcomes, its work history file provides an unusually complete picture of employment for a cohort of young workers during a period when they have made transitions from school to work. This includes records of virtually every job held, as a result, it is ideal for my study. The original NLSY-79 sample consists of 12686 men and women (age 14-22 in 1979) who were interviewed annually between 1979 and 1994 and biennially from 1996 to the present. There are three subsamples in the NLSY-79: a cross-sectional sample representative of young people; a supplemental sample designed to oversample Hispanic, Black, and economically disadvantaged White youth; and a sample designed to represent the population of those enlisted in one of the four branches of the military. I exclude from my analysis the military subsample because following the 1984 interview, the military subsample were no longer eligible for interview and it is hard to construct a long enough employment series for respondents from this subsample.

There are 5579 males in the original NLSY-79 sample after eliminating the military respondents.
I exclude those employment and wage observations from before a person leaves school and begins to accumulate labor market experience, and only count job changes from that point. My definition of the school-to-work transition date follows that of Altonji and Pierret (2001): the month and year of the respondent’s most recent enrollment in school at the first interview when the respondent is not currently enrolled. I lose 49 individuals from the original sample because their school exit date is indeterminate according to this definition. I also exclude 1137 individuals whose labor market entry occurs before January 1978. Detailed information on employment activities is only reported from that date onwards in the work history file, so I can not construct accurate measures of overall mobility, work experience, and job tenure for workers who start their careers before January 1978. Additionally, I delete 47 individuals because their actual labor market experience or job seniority is indeterminate and another 12 individuals whose wage information is unreasonable, which brings the sample size down to 4334. Furthermore, 202 individuals in the sample did not take the Armed Services Vocational Aptitude Battery (ASVAB) tests which are used by the NLSY-79 to construct the AFQT score. After dropping them, the remaining sample consists of 4132 individuals with 48617 person-year observations.

Table 1 contains summary statistics for observations used in the analysis. Actual labor market experience is the number of weeks in which the worker works more than 30 hours divided by 52 after the transition from school to work. I do not count part-time employment, self-employment, time spent working without pay, time spent unemployed, and time spent out of the labor force. Job tenure is calculated as the number of weeks divided by 52 spent in full-time employment with the same employer. The wage measure is the hourly wage from the NLSY-79 work history file.

---

20 Alternatively, Farber and Gibbons (1996) define a transition as occurring if the worker is classified as non-working for at least one year, followed by at least two consecutive years classified as working, where a worker is classified as working when she has worked at least 26 weeks, and during these weeks at least 30 hours, since the last interview.

21 The AFQT score is derived as the sum of the raw scores from the following four sections of the ASVAB: arithmetic reasoning, word knowledge, paragraph comprehension, and one half of the score from numerical operations sections.

22 The ASVAB was administered to the NLSY-79 respondents in 1980, thus, different respondents took it at different ages. To eliminate age effects, I standardize the AFQT score within each birth cohort.

23 For the individuals who work more than one job at a point in time, I only consider the job for which the respondent works most during the week.

Data Source: Author's calculations using NLSY-79. The sample consists of 4132 individuals with 48617 observations in the years from 1979 to 2000. See the Data section of the paper for details of sample construction.

Wages are deflated by the Consumer Price Index with 2002 as the base year, values below $1 and above $300 are considered unreasonable and dropped.²⁴

The job mobility count is obtained from the work history file of the NLSY-79, which reports the starting dates for the jobs held at the time of each interview, as well as for up to five jobs²⁵ that began and ended since the last interview. I link all the jobs across survey years²⁶ and construct a complete employment history for each individual in the sample. The frequency of job mobility is calculated as the individual’s mean number of prior job separations as of time t. Table 2 shows the distribution of the number of job separations by each worker during the first 2, 5, and 10 years of his career as well as the total number of jobs held.

The average number of job separations in the first ten years is 5.6 with a standard deviation of 4.0. The mean number of jobs actually held²⁷ is 6.2 with a standard deviation of 4.0. Table 2 also illustrates that only 3% of individuals experience no job changes in the first 10 years of their career, while around 10% of workers remain with their initial employers during the first five years.

²⁴I tried other cutoff values, such as $0.5 and $200. My empirical results are not sensitive to the changes of these values that define unreasonable wage observations. See Bollinger and Chandra (2005) for more on this issue.

²⁵The NLSY-79 collects information on all jobs held by a respondent since the last interview, however, the percentage of respondents who report more than five jobs in each survey year is less than 1%.

²⁶As the same employer can receive different job codes across survey years, it is necessary to use beginning and ending dates as well as a series of matching variables to determine the job code in the previous survey for every employer in the current survey and to decide whether it is a new job.

²⁷Topel and Ward (1992) find that the average worker holds 6.1 jobs by the time he or she has eight years of potential labor market experience in their longitudinal employer-employee data.

Data Source: Author's calculations using NLSY-79. For a description of the sample used, see Data section of the paper.

Notes: All the estimates are weighted by the NLSY-79 sampling weights. Job separation counts and total number of jobs held are obtained from the NLSY-79 work history file which reports the starting and ending dates for jobs held at the time of each interview and the same information for up to 5 jobs which began and ended since the last interview.

and 38% for the first two years. At the other extreme, 11% of individuals separate from 10 or more employers within the first ten years after the school to work transition, that is, they average over one job separation per year for the 10-year period. Table 2 demonstrates that the typical individual in the sample is quite mobile early in his career.

The data on job separations also suggest that job mobility slows over time, while it can not be said to be solely attributable to the intensified adverse selection, it is at least consistent with the three-period model where outside employers take the employment history into account. Neither the symmetric employer learning model nor the two-period mover-stayer model implies a decline in job turnovers. In those models, the probability of job separation is constant over time conditional on innate ability. About 30% of the sample undergoes no job changes during the second five years, and 46% undergoes at most one job separation during that time period.

Throughout the paper, I use the total number of job separations rather than the number of voluntary job separations. It is not very clear how to distinguish between involuntary and voluntary job separations in the NLSY-79. The NLSY-79 codes a large number of reported reasons for each
job separation, including “bad working condition”, “own illness”, “found better job”, “spouse changed jobs”, etc. If I delete all job separations corresponding to “layoff” and “discharged/fired”, then 70% of all the job separations remain. However, those remaining job separations still include ones caused by family reasons as well as ones caused by “found better job” and “pay too low”. Moreover, the explanation for over 25% of all job exits is coded as either “other” or missing, so I must either eliminate those jobs or arbitrarily assign them to voluntary or involuntary categories.

5 Econometric Specification and Empirical Results

One of the empirical implications of an employer learning model in which information about a worker’s productivity is public is a zero correlation between the worker’s innate ability and his probability of changing jobs. Both the two-period mover-stayer model of asymmetric employer learning and my three-period extension challenge this by showing that the average quality of the job-changing pool is lower than that of the pool of stayers. What differentiates these two versions of the asymmetric information model is the prediction regarding how the relationship between ability and the job change probability changes over time. In the absence of learning by outside employers, the mover-stayer story implies a constant correlation between $\eta$ and the probability of job change. On the other hand, the information accumulation by potential employers through the observed job mobility history implies that this relationship becomes weaker and weaker over time.

I test this implication of the learning model by estimating a probit model where the dependent variable is an indicator of whether the worker experiences any job changes,

$$
Pr(\text{JobChange}_{i,t} = 1) = \Phi(\beta_0 + \beta_1 AFQT_i + \beta_2 (Exp_{i,t}/10) + \beta_3 (AFQT_i \times Exp_{i,t}/10) + \beta'_X X_{i,t}),
$$

where $Exp_{i,t}$ is the actual labor market experience and $X_{i,t}$ is a vector of other control variables. Throughout the empirical analysis, I normalize all the interactions between schooling and the $AFQT$ score with experience to represent the change in the regression slope between $Exp = 0$ and $Exp = 10$. Also, all of the standard errors reported in this paper are based on White/Huber

Data Source: Author’s calculations using NLSY-79. For a description of the sample used, see Data section of the paper.

Notes: All the probit marginal effects are means of the individual marginal effects. The dependent variable is a dummy variable for at least one job separation during the year. Model (2) also includes experience/10 as independent variable. Model (3) also includes experience/10, black, hispanic, industry and occupation dummies, and year dummies as independent variables. Model (4) includes school enrollment status at the ASVAB test date, highest grade completed at ASVAB test date as additional independent variables besides the ones in model (3). The standard errors are in parentheses and are White/Huber standard errors accounting for potential correlation at the individual level. The standard errors of the marginal effects are derived through the delta-method. * signifies significance at the 10% level, ** at the 5% level and *** at the 1% level.

standard errors that account for arbitrary forms of heteroskedasticity and correlation among the multiple observations for each individual. All of the estimates in this paper are weighted by the sampling weights provided by the NLSY-79. Coefficients $\beta_1$ and $\beta_3$ should both be zero under the assumption of public learning. All of the asymmetric learning models imply a negative $\beta_1$, but only a model with signaling effect of the job mobility history implies positive coefficient $\beta_3$.

The results are presented in Table 3. Column (1) in the table is the mean marginal effect estimated from a probit model where the standardized AFQT score is the only explanatory variable. An one standard deviation increase in the test score is accompanied by a 3.6 percentage point decrease of the probability of changing jobs. This preliminary evidence clearly rejects the symmetric employer learning hypothesis by a highly statistically significant probit marginal effect associated with the AFQT score. To distinguish the two types of asymmetric learning hypotheses, column (2) estimates the same probit with experience and the interaction between the AFQT score and experience as additional independent variables. The mean marginal effect on the AFQT score remains statistically significant, and there is a positive and statistically significant estimate for the interaction term of the AFQT score and labor market experience. The decreasing time path of the
impact of the $AFQT$ score on the probability of changing jobs is an unique prediction from the three-period adverse selection model following the closing of the informational gap between current and outside employers about the productivity of the workers. The estimated marginal effect of 0.026 strongly suggests that not only does the current employer learns, but potential employers also accumulate new information about a worker’s innate ability.

Including additional covariates in the probit regression, column (3) controls for race, industry and occupation affiliation, and year effects. These control variables weaken the correlation between the $AFQT$ score and job mobility, but by no means eliminate it. The probit marginal effects associated with the $AFQT$ score and the interaction term are still statistically significant and qualitatively tell the same story as column (2). Hansen, Heckman, and Mullen (2004) find strong evidence in the NLSY-79 suggesting that schooling is an important determinant of measured achievement such as the $ASVAB$ scores,\(^{28}\) their estimated increase in the $AFQT$ score per year of education for the average person is 0.17 standard deviation. To deal with the schooling effect on the test score, I construct the educational level and school enrollment status at the $ASVAB$ test date for each individual in the sample\(^{29}\) and include them in the probit regression of column (4). Putting schooling information as of the test date into the model substantially reduces the magnitude of the probit coefficients, the estimated marginal effects of the $AFQT$ score and the interaction term stand at -0.012 and 0.014, respectively, both are statistically significant at the 5% level, and the overall conclusion is the same as that drawn from column (2) and column (3).

To summarize, the probit estimates shown in Table 3 are consistent with an asymmetric employer learning model in which both the incumbent and the outside employers gather information about the worker’s unobserved productivity. The negative and statistically significant mean marginal effect of the $AFQT$ score on the job change probability rejects the public learning hypothesis and

\(^{28}\)See Neal and Johnson (1996), Cascio and Lewis (2006) for a similar result.

\(^{29}\)The $ASVAB$ was administered during July–October 1980. Respondents in the NLSY-79 were interviewed during January–August 1980 and January–July 1981. The NLSY-79 also includes a measure of schooling and enrollment status as of May 1 of each survey year. Since the academic year commonly ends in June, individuals advance to a higher completed grade level in June. I use the highest grade completed and enrollment status as reported in the 1980 survey as schooling and enrollment values at the test date if the interview was conducted during July–August 1980, otherwise we use the variables reported in 1981 if the interview was conducted during January-April 1981. For the remaining respondents, I use the variables for May 1, 1981.
the gradually decreasing association between the test score and the probability of job separation is at odds with the two-period mover-stayer model.

To further distinguish the two versions of asymmetric employer learning models, one without outside employers learning and the other with potential firms learning through the employment history of the job candidate, I make use of the empirical framework advanced by Farber and Gibbons (1996) and Altonji and Pierret (2001). Under the assumption of pure public learning, Altonji and Pierret (2001) estimate a version of the standard earnings equation with schooling and the $AFQT$ score interacting with labor market experience

\[ \ln w_{i,t} = \alpha_0 + \alpha_1 \text{Schooling}_i + \alpha_2 AFQT_i + f(Exp_{i,t}/10) + \alpha_3 (\text{Schooling}_i \times Exp_{i,t}/10) + \alpha_4 (AFQT_i \times Exp_{i,t}/10) + \alpha'_X X_{i,t} + \xi_{i,t}, \quad (23) \]

where the log wage for the $i$th worker at time $t$ depends on his schooling, his $AFQT$ score, labor market experience, and other observable characteristics $X_{i,t}$. Their model shows that when the $AFQT$ score is included in the regression as an ability measure, the time path of the coefficient on schooling declines with experience while the coefficient on the $AFQT$ score increases with labor market experience. As employers learn more about the productive ability of a worker, they rely less on the easily observable variables such as education in the wage setting process. Note that my model in Section 3 explicitly demonstrates that their implications regarding the signs of $\alpha_3$ and $\alpha_4$ also hold even when the information about the worker’s productivity is asymmetric.

Table 4 fits my sample into their wage regressions. In addition to the explanatory variables shown in the table, all of the regressions control for race, a cubic in experience, industry and occupation, year effects, education interacted with year effects, and Black and Hispanic interacted with year effects. The first two columns report OLS estimates of (23). Columns three and four report two stage least squares (2SLS) estimates using potential experience as instrument for actual labor market experience.\(^{30}\) Looking across the columns, the two sets of coefficient estimates tell

\(^{30}\)Altonji and Pierret (2001) argue that the implications of employer learning for the wage equation may change if the intensity of work experience conveys information to employers about worker quality.

Data Source: Author’s calculations using NLSY-79. For a description of the sample used, see Data section of the paper. Notes: All the estimates are weighted by the sampling estimates provided by the NLSY-79. The dependent variable is the natural log of the respondent's hourly wage. All the regressions in the table contain a cubic in experience, black, hispanic, industry and occupation affiliation, year effects, education interacted with year effects, interactions between black and year effects, and between hispanic and year effects. The standard errors are in parentheses and are White/Huber standard errors accounting for potential correlation at the individual level. * signifies significance at the 10% level, ** at the 5% level and *** at the 1% level.

the same story and confirm the empirical findings of Altonji and Pierret (2001) that the impact of the AFQT score on wages increases with labor market experience and the coefficient on years of schooling decreases with experience.

While these estimates support the view that employers acquire new information about workers’ productivity over time, they do not allow us to distinguish among public learning, asymmetric learning without the outside employer accumulating new information, and the three-period model developed in the Section 3. When the recruiting employers gather new information about the ability of the worker through his employment history, my model predicts a declining difference between the impacts of ability on wage offers from the incumbent and the outside firms with increasing job mobility, and therefore a negative coefficient for the interaction term involving the AFQT score,
job tenure, and the frequency of job mobility. I estimate the following wage regression,

$$\ln w_{i,t} = \gamma_0 + \gamma_1 \text{Schooling}_i + \gamma_2 \text{AFQT}_i + f_1(\text{Exp}_{i,t}/10) + f_2(\text{Tenure}_{i,t}/10) + \gamma_3 \text{Freq}_{i,t} +$$

$$\gamma_4(\text{Schooling}_i \times \text{Exp}_{i,t}/10) + \gamma_5(\text{AFQT}_i \times \text{Exp}_{i,t}/10) + \gamma_6(\text{AFQT}_i \times \text{Tenure}_{i,t}/10) +$$

$$\gamma_7(\text{AFQT}_i \times \text{Freq}_{i,t}) + \gamma_8(\text{AFQT}_i \times \text{Tenure}_{i,t}/10 \times \text{Freq}_{i,t}) + \gamma_X' X_{i,t} + u_{i,t},$$

(24)

where $\text{Tenure}_{i,t}$ denotes job tenure and $\text{Freq}_{i,t}$ denotes the $i$th worker’s frequency of job mobility as of time $t$. The closing informational gap between the current and outside firms through employment history implies that $\gamma_8 < 0$. On the other hand, if the outside employers ignore the information concerning the worker’s innate ability contained in the job mobility history as described in the two-period model, or if their learning process occurs through other channels, then we would expect to find $\gamma_8 = 0$.

The OLS estimates of (24) are displayed in Table 5. Other covariates that I control for are a cubic in experience, a cubic in job tenure, race, industry and occupation, year effects, education interacted with experience, education interacted with year effects, and interactions between race dummies and year effects. Column (1) provides the regression estimates before controlling the measure of job mobility. It coincides with the existing tests for the asymmetric employer learning model such as those in Schonberg (2005). If employer learning is private, the impact of ability on the wage offer of the current employer exceeds that of the outside firms, which predicts $\gamma_6 > 0$ in (24), as opposed to the case of pure symmetric learning which implies $\gamma_6 = 0$. In line with Schonberg (2005), my estimate for the coefficient associated with the interaction term between the AFQT score and job tenure shows a positive sign that is consistent with the asymmetric information model but fails to pass the significance test at conventional levels. Schonberg (2005) only finds a marginally significant estimate for $\gamma_6$ after controlling for interactions between the AFQT score and higher order tenure terms for her university graduates sample.

Column (2) of Table 5 estimates a complete version of (24) and paints a very different picture. Not only does the positive and significant coefficient estimate of 0.021 for the AFQT score and

Data Source: Author's calculations using NLSY-79. For a description of the sample used, see Data section of the paper.

Notes: All the estimates are weighted by the sampling weights provided by the NLSY-79. The dependent variable is the natural log of the respondent's hourly wage. All regressions in the table contain a cubic in experience, a cubic in job tenure, black, hispanic, industry and occupation affiliation, year effects, education interacted with experience, education interacted with year effects, interactions between black and year effects, and between hispanic and year effects. The standard errors are in parentheses and are White/Huber standard errors accounting for potential correlation at the individual level. * signifies significance at the 10% level, ** at the 5% level and *** at the 1% level.
job tenure interaction favor the asymmetric employer learning, but the -0.013 associated with the interaction among the AFQT score, job tenure, and the frequency of job mobility also suggests that outside employers indeed acquire knowledge about the worker’s ability through his job change pattern and the informational discrepancy between the incumbent and potential employers in turn diminishes with experience. Conditioning on job tenure, I still see a positive coefficient estimate of 0.049 for the variable interacting experience and the AFQT score, which reinforces the conclusion that learning on the labor market is not purely asymmetric. I also find a negative coefficient estimate for the frequency of job mobility\(^{31}\) which suggests that early-career mobility does little to help but can do a significant amount to hurt wages. Although this may not be a defining implication from the model, it is consistent with the intensified adverse selection story.

As a time-varying signal of the worker ability, the availability to the market of job mobility history also has implications for the role played by the time-invariant observables that the employers initially use to statistically discriminate among workers. To study how the worker’s career path affects the employer learning through easy-to-observe characteristics like schooling, I estimate a wage equation of the type

\[
\ln w_{i,t} = \lambda_0 + \lambda_1 \text{Schooling}_i + \lambda_2 \text{AFQT}_i + f_1(\text{Exp}_{i,t}/10) + f_2(\text{Tenure}_{i,t}/10) + \lambda_3 \text{Freq}_{i,t} +
\]

\[
\lambda_4(\text{Schooling}_i \times \text{Exp}_{i,t}/10) + \lambda_5(\text{AFQT}_i \times \text{Exp}_{i,t}/10) + \lambda_6(\text{Schooling}_i \times \text{Ten}_{i,t}/10) +
\]

\[
\lambda_7(\text{AFQT}_i \times \text{Tenure}_{i,t}/10) + \lambda_8(\text{Schooling}_i \times \text{Freq}_{i,t}) + \lambda_9(\text{AFQT}_i \times \text{Freq}_{i,t}) + \lambda_X X_{i,t} + v_{i,t}.
\]

(25)

Table 6 reports the OLS estimates of (25) where X contains the same additional variables as in Table 5. Column (1) excludes the job mobility measure and its interactions with schooling and the AFQT score. Although the general pattern of the coefficients on the interactions between the AFQT score and schooling with experience suggested by the learning model is still borne out by the data, the highly imprecise estimates for \(\lambda_6\) and \(\lambda_7\) tell us nothing about the nature

\(^{31}\)See Light and McGarry (1998) for similar findings.

Data Source: Author's calculations using NLSY-79. For a description of the samples used, see Data section of the paper.

Notes: All the estimates are weighted by the sampling weights provided by the NLSY-79. The dependent variable is the natural log of the respondent's hourly wage. All regressions in the table contain a cubic in experience, a cubic in job tenure, black, hispanic, industry and occupation affiliation, year effects, education interacted with year effects, interactions between black and year effects, and between hispanic and year effects. The standard errors are in parentheses and are White/Huber standard errors accounting for potential correlation at the individual level. * signifies significance at the 10% level, ** at the 5% level and *** at the 1% level.
of employer learning. In column (2) of Table 6, the estimates support the three-period model in which potential employers learn from the job mobility patterns. In particular, the negative and significant coefficient estimate for the interaction term of schooling and the frequency of job mobility implies that education plays less of a signaling role as outside firms rely more on employment history to assess the value of the worker’s productivity. Information revelation as an immediate consequence of intensified adverse selection helps the recruiting firms to become better informed about the quality of the workers in the job-changing pool. Also, the coefficient on the interaction of education and job tenure is negative, though only significant at 10% level, it provides suggestive evidence that potential employers depend more, relative to the incumbent employer, on schooling to determine their wage offers. Taken together, these empirical results strongly support the aforementioned three-period model in which not only the incumbent employers learn, but the outside firms also actively extract information from workers’ employment histories.

6 Conclusions

How do firms learn about their workers’ productivity? Do they use easily observed characteristics such as education and race to statistically discriminate among their workers? Do current employers have more information about the worker’s productivity than outside firms? If they do, what can outside firms do to minimize their informational disadvantage? During the past decade, labor economists have developed employer learning models to better understand these questions. Although consensus has been reached, both theoretically and empirically, on the existence of employer learning in the market place, our understanding of whether learning is asymmetric and how the information asymmetry is resolved remains unsatisfactory. This paper builds a learning model under the hypothesis that incumbent employers have superior information about the productivity of the workers. A special feature of my model is that outside employers, by observing workers’ job mobility histories, also have access to information about the workers’ ability. This attribute differentiates the present model from existing work on asymmetric employer learning that are based
on two-period mover-stayer model. My model also includes a match-specific productivity component that is known ex ante, I show that because the distribution of match quality is independent and the quality of previous match is irrelevant to the newly formed job match, the presence of match-specific productivity does not alter the nature of employer learning about the innate ability of their workers.

It is important to underscore the limits of this study. The literature has long recognized that human capital accumulation may undermine the predictions from learning models. Although the empirical evidence of intensified adverse selection established through our probit estimates is based on a robust feature of the model, the estimates of the wage regressions, especially the coefficient associated with the interaction between the $AFQT$ score and job seniority, also fit a model in which ability aids the acquisition of specific human capital. This complementarity between ability and specific capital implies that more able workers command higher returns to job tenure, which implies a positive coefficient for the interaction term between the $AFQT$ score and job seniority. It is very difficult to distinguish the present model from a specific human capital model, I can only partially address this concern, following Schonberg (2005), by looking at differential returns to job tenure by education level. The estimate from column (2) of Table 6, even though only marginally significant, implies lower returns for higher educated workers. If we expect individuals with more years of schooling to benefit more from job seniority as the human capital theories imply, my negative coefficient is at odds with such a prediction. I also rule out the experience good nature of job match, analysis of such an asymmetric employer learning model with learning about the match quality is rather complex and beyond the scope of the current study.

To conclude, the empirical evidence from the NLSY-79 broadly supports the implications from the three-period model: ability is negatively correlated with the probability of changing jobs and this association weakens as young workers unfold their careers; accruing information through observing the employment history on the part of outside firms gradually eliminates the knowledge gap between them and incumbent firms, which makes the difference of the impacts of ability on

---

32See Altonji and Spletzer (1991) for such an example.
wage rates smaller between them and the incumbent firm, and allows them to be dependent less on the easy-to-observe characteristics of the workers.
